1 Automatic Differentiation in Machine Learning: a Survey

Derivatives, mostly in the form of gradients and Hessians, are ubiquitous in machine learning. Automatic differentiation (AD) is a family of techniques similar to but more general than backpropagation for efficiently and accurately evaluating derivatives of numeric functions expressed as computer programs. Until very recently, the fields of machine learning and AD have largely been unaware of each other and, in some cases, have independently discovered each other's results. Despite its relevance, general-purpose AD has been missing from the machine learning toolbox, a situation slowly changing with its ongoing adoption under the names dynamic computational graphs and differentiable programming.

1.1 Introduction

Methods for the computation of derivatives in computer programs can be classified into four categories:

Method	Pros	Cons
Manual Differentiation		-Time consuming
		-Error prone
Numerical Differentiation	Easier to implement	-Highly inaccurate due to round-off
	than the manual	and truncation errors
	method	-Scales poorly for gradients
		$(\Rightarrow \text{inappropriate for machine learning})$
Symbolic Differentiation	Addresses the weaknesses	Often results in complex and cryptic
	of both the manual	expressions plagued with the problem
	and numerical methods	of expression swell

Furthermore, manual and symbolic methods require models to be defined as closed-form expressions, ruling out or severely limiting algorithmic control flow and expressivity.

The last and most powerful method is represented by Automatic Differentiation (AD) which performs a non-standard interpretation of a given computer program by replacing the domain of the variables to incorporate derivative values and redefining the semantics of the operators to propagate derivatives per the chain rule of differential calculus. We would like to stress that AD as a technical term refers to a specific family of techniques that compute derivatives through accumulation of values during code execution to generate numerical derivative evaluations rather than derivative expressions. This allows accurate evaluation of derivatives at machine precision with only a small constant factor of overhead and ideal asymptotic efficiency.

In contrast with the effort involved in arranging code as closed-form expressions under the syntactic and semantic constraints of symbolic differentiation, AD can be applied to regular code with minimal change, allowing branching, loops, and recursion.

In machine learning, a specialized counterpart of AD known as the backpropagation algorithm has been the mainstay for training neural networks, with a colorful history of having been reinvented at various times by independent researchers. In simplest terms, backpropagation models learning as gradient descent in neural network weight space, looking for the minima of an objective function. The required gradient is obtained by the backward propagation of the sensitivity of the objective value at the output, utilizing the chain rule to compute partial derivatives of the objective with respect to each weight. The resulting algorithm is essentially equivalent to transforming the network evaluation function composed with the objective function under reverse mode AD, which, as we shall see, actually generalizes the backpropagation idea.

1.2 What AD Is Not

Without proper introduction, one might assume that AD is either a type of numerical or symbolic differentiation. Confusion can arise because AD does in fact provide numerical values of derivatives (as opposed to derivative expressions) and it does so by using symbolic rules of differentiation (but keeping track of derivative values as opposed to the resulting expressions), giving it a two-sided nature that is partly symbolic and partly numerical.

1.2.1 AD Is Not Numerical Differentiation

Numerical differentiation is the finite difference approximation of derivatives using values of the original function evaluated at some sample points. In its simplest form, it is based on the limit definition of a derivative. For example, for a multivariate function $f: \mathbb{R}^n \to \mathbb{R}$ one can approximate the gradient $\nabla f = (\frac{\partial f}{\partial x_1}, ..., \frac{\partial f}{\partial x_n})$ using

$$\frac{\partial f(x)}{\partial x_i} \approx \frac{f(x + he_i) - f(x)}{h}$$

where e_i is the i-th unit vector (it is used to modify only the i-th direction of the point x) and h > 0 is a small step size.

Let's summarize the pros and cons of numerical differentiation with the following table:

Pros	Cons	
Simple to implement	$-\mathrm{O}(\mathrm{n})$ evaluations of f for a gradient in n dimensions	
	-Careful selection of the step size h	

Numerical approximations of derivatives are inherently ill-conditioned and unstable because using the limit definition of the derivative for finite difference approximation then one commits both cardinal sins of numerical analysis: "thou shalt not add small numbers to big numbers", and "thou shalt not subtract numbers which are approximately equal". This is due to the introduction of truncation and round-off errors inflicted by the limited precision of computations and the chosen value of the step size h. Truncation error tends to zero as $h \to 0$. However, as h is decreased, round-off error increases and becomes dominant.

Numerical Differentiation and ML The major obstacle to applying numerical differentiation to machine learning is the complexity O(n), because n can be as large as millions or billions in state-of-the-art deep learning models. In contrast, approximation errors would be tolerated in a deep learning setting thanks to the well-documented error resiliency of neural network architectures.

1.2.2 AD Is Not Symbolic Differentiation

Symbolic differentiation is the automatic manipulation of expressions for obtaining derivative expressions, it is carried out by applying transformations representing rules of differentiations such as

$$\frac{d}{dx}(f(x) + g(x)) \to \frac{d}{dx}f(x) + \frac{d}{dx}g(x)$$
$$\frac{d}{dx}(f(x) \cdot g(x)) \to \left(\frac{d}{dx}f(x)\right)g(x) + f(x)\left(\frac{d}{dx}g(x)\right)$$

When formulae are represented as data structures, symbolically differentiating an expression tree is a perfectly mechanistic process.

Let's summarize the pros and cons of numerical differentiation with the following table:

Pros	Cons
In optimization, symbolic derivatives can	No efficient runtime calculation of derivative
give valuable insight into the structure of	values because symbolic expression can get
the problem domain and produce analytical	exponentially larger than the expression
solution of extrema that can eliminate the	whose derivative they represent.
need for derivative calculation altogether.	

Automatic differentiation Solution Automatic differentiation tries to solve the efficiency problem of Symbolic Differentiation. When we are concerned with the accurate numerical evaluation of derivatives and not so much with their actual symbolic form, it is in principle possible to significantly simplify computations by storing only the values of intermediate sub-expressions in memory. Moreover, for futher efficiency, we can interleave as much as possible the differentiation and simplification steps. This interleaving idea forms the basis of AD and provides an account of its simplest form: apply symbolic differentiation at the elementary operation level and keep intermediate numerical results, in lockstep with the evolution of the main function.

1.3 AD and Its Main Modes

AD can be thought as performing a non-standard interpretation of a computer program where this interpretation involves augmenting the standard computation with the calculation of various derivatives. All numerical computations are ultimately compositions of a finite set of elementary operations for which derivatives are known and combining the derivatives of the constituent operations through the chain rule gives the derivative of the overall composition.

Given a function $f: \mathbb{R}^n \to \mathbb{R}^m$, an evolution trace is constructed using intermediate variables v_i such that

- variables $v_{i-n} = x_i$, i = 1, ..., n are the input variables,
- variables v_i , i = 1, ..., l are the working (intermediate) variables, and
- variables $y_{m-i} = v_{l-i}$, i = m-1, ..., 0 are the output variables.

Example Let us consider the function $f(x_1, x_2) = ln(x_1) + x_1 \cdot x_2 - sin(x_2)$. The computational graph of this function is the following

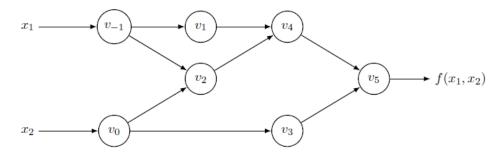

Figure 1: Computational graph of the function $f(x_1, x_2) = ln(x_1) + x_1 \cdot x_2 - sin(x_2)$

This graph is useful for visualizing dependency relationships between intermediate variables. We will see in the next sections the evolution traces for forward mode and reverse mode related to this example.

An important point to note here is that AD can differentiate not only closed-form expressions in the classical sense, but also algorithm making use of control flow such as branching, loops, recursion, and procedure calls, giving it an important advantage over symbolic differentiation which severely limits such expressivity. This is thanks to the fact that any numeric code will eventually result in a numeric evaluation trace with particular values of the input, intermediate, and output values, which are the only things one needs to know for computing derivatives using chain rule composition, regardless of the specific control flow path that was taken during execution.

1.3.1 Forward Mode

AD in forward accumulation mode is the conceptually most simple type.

Example Let us consider the evalutation trace of the function $f(x_1, x_2) = \ln(x_1) + x_1 \cdot x_2 - \sin(x_2)$ give on the left-hand side in Figure 2 and in graph form in Figure 1. In order to compute the derivative of f with respect to x_1 , we start by associating with each intermediate variable v_i a derivative $\dot{v}_i = \frac{\partial v_i}{\partial x_1}$. Then applying the chain rule to each elementary operation in the forward primal trace, we generate the corrisponding tangent derivative trace, given on the right-hand side in Figure 2. Evaluating the primals v_i in lockstep with their corrisponding tangent \dot{v}_i gives us the required derivative in the final variable $\dot{v}_5 = \frac{\partial y}{\partial x_1}$.

Forward Primal Trace		F	Forward Tangent (Derivative) Trace			
$v_{-1} = x_1$	=2	1	\dot{v}_{-1}	$\dot{x}_1 = \dot{x}_1$	= 1	
$v_0 = x_2$	=5		\dot{v}_0	$=\dot{x}_2$	=0	
$v_1 = \ln v_{-1}$	$= \ln 2$		\dot{v}_1	$=\dot{v}_{-1}/v_{-1}$	= 1/2	
$v_2 = v_{-1} \times v_0$	$=2\times5$		\dot{v}_2	$=\dot{v}_{-1}\times v_0+\dot{v}_0\times v_{-1}$	$= 1 \times 5 + 0 \times 2$	
$v_3 = \sin v_0$	$=\sin 5$		\dot{v}_3	$=\dot{v}_0 \times \cos v_0$	$= 0 \times \cos 5$	
$v_4 = v_1 + v_2$	= 0.693 + 10		\dot{v}_4	$= \dot{v}_1 + \dot{v}_2$	=0.5+5	
$v_5 = v_4 - v_3$	= 10.693 + 0.959		\dot{v}_5	$= \dot{v}_4 - \dot{v}_3$	=5.5-0	
$y = v_5$	= 11.652	\downarrow	\dot{y}	$=\dot{v}_{5}$	= 5.5	

Figure 2: Forward mode AD example, with $y = f(x_1, x_2) = ln(x_1) + x_1 \cdot x_2 - sin(x_2)$ evaluated at $(x_1, x_2) = (2, 5)$ and setting $\dot{x_1} = 1$ to compute $\frac{\partial y}{\partial x_1}$.

1.3.2 Reverse Mode

AD in the reverse accumulation mode corresponds to a generalized backpropagation algorithm, in that it propagates derivatives backward from a given output. This is done by complementing each intermediate variable v_i with an adjoint $\overline{v}_i = \frac{\partial y_j}{\partial v_i}$ which represents the sensitivity of a considered output y_j with respect to changes in v_i . In the case of backpropagation, y would be a scalar corresponding to the error E.

In reverse mode AD, derivatives are computed in the second phase of a two-phase process. In the first phase, the original function code is run forward, populating intermediate variables v_i and recording the dependencies in the computational graph through a book-keeping procedure. In the second phase, derivatives are calculated by propagating adjoints \bar{v}_i in reverse, from the outputs to the inputs.

Backpropagation Algorithm After performing the forward pass through the network, we need to calculate the loss function which is used to calculate the distance between the predicted value and the actual value. Backpropagation aims to minimize the cost function by adjusting network's weights and biases. The level of adjustment is determined by the gradients of the loss function with respect to those parameters. Compute those gradients happens using a technique called *chain rule*.

Example Returning to the example $y = f(x_1, x_2) = \ln(x_1) + x_1 \cdot x_2 - \sin(x_2)$, in Figure 3 we see the adjoint statements on the right-hand side, corresponding to each original elementary operation on the left-hand side.

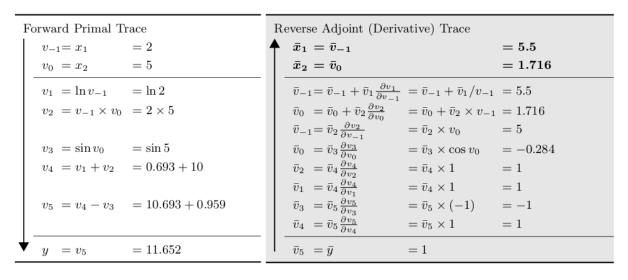

Figure 3: Reverse mode AD example with $y = f(x_1, x_2) = \ln(x_1) + x_1 \cdot x_2 - \sin(x_2)$ evaluated at $(x_1, x_2) = (2, 5)$. After the forward evaluation of the primals on the left, the adjoint operations on the right are evaluated in reverse. Note that both $\overline{x}_1 = \frac{\partial y}{\partial x_1}$ and $\overline{x}_2 = \frac{\partial y}{\partial x_2}$ are computed in the same reverse pass, starting from the adjoint $\overline{v}_5 = \overline{y} = \frac{\partial y}{\partial y} = 1$.

In simple terms, we are interested in computing the contribution $\overline{v}_i = \frac{\partial y_j}{\partial v_i}$ of the change in each variable v_i to the change in the output y. Taking the variable v_0 as an example, we see in Figure 1 that the only way it can affect y is through affecting v_2 and v_3 , so its contribution to the change in y is given by

$$\frac{\partial y}{\partial v_0} = \frac{\partial y}{\partial v_2} \frac{\partial v_2}{\partial v_0} + \frac{\partial y}{\partial v_3} \frac{\partial v_3}{\partial v_0}$$

where $\overline{v}_2 = \frac{\partial y}{\partial v_2}$ and $\overline{v}_3 = \frac{\partial y}{\partial v_3}$. In Figure 3, this contribution is computed in two incremental steps

$$\overline{v}_0 = \overline{v}_3 \frac{\partial v_3}{\partial v_0}$$
 $\overline{v}_0 = \overline{v}_0 + \overline{v}_2 \frac{\partial v_2}{\partial v_0}$

lined up with the lines in the forward trace from which these expressions originate.

After the forward pass on the left-hand side, we run the reverse pass of the adjoints on the right-hand side, starting with $\overline{v}_5 = \overline{y} = \frac{\partial y}{\partial y} = 1$. In the end we get the derivatives $\overline{x}_1 = \frac{\partial y}{\partial x_1}$ and $\overline{x}_2 = \frac{\partial y}{\partial x_2}$ in just one reverse pass.

Forward Mode Advantage An important advantage of the reverse mode is that it is significantly less costly to evaluate (in terms of operation count) than the forward mode for functions with a large number of inputs. In the extreme case of $f: \mathbb{R}^n \to \mathbb{R}$, only one application of the reverse mode is sufficient to compute the full gradient $\nabla f = \left(\frac{\partial y}{\partial x_1}, ..., \frac{\partial y}{\partial x_n}\right)$, compered with the n passes of the forward mode needed for populating the same. Because machine learning practice principally involves the gradient of a scalar-valued objective with respect to a large number of parameters, this establishes the reverse mode, as opposed to the forward mode, as the mainstay technique in the form of the backpropagation algorithm.

1.4 AD and Machine Learning

Areas where AD has seen use include optimization, neural networks, computer vision, natural language processing, and probabilistic inference.

1.4.1 Gradient-Based Optimization

Gradient-based optimization is one of the pillars of machine learning. Given an objective function $f: \mathbb{R}^n \to \mathbb{R}$, classical gradient descent has the goal of finding (local) minima $\mathbf{w}^* = argmin_{\mathbf{w}} f(\mathbf{w})$ via updates of the form $\Delta \mathbf{w} = -\eta \nabla f$ where $\eta > 0$ is a step size (known as learning rate). Gradient-based methods make use of the fact that f decreases steepest if one goes in the direction of the negative gradient. The convergence rate of gradient-based methods is usually improved by adaptive step-size techniques that adjust the step size η on every iteration. As we have seen, for large n, reverse mode AD provides a highly efficient method for computing gradients.

1.4.2 Neural Networks, Deep Learning, Differentiable Programming

Training of a neural network is an optimization problem with respect to its set of weights, which can in principle be addressed by using any method ranging from evolutionary algorithms to gradient-based methods or the mainstay stochastic gradient descent and its many variants.

As we have seen, the backpropagation algorithm is only a special case of AD: by applying reverse mode AD to an objective function evaluating a network's error as a function of its weights, we can readily compute the partial derivatives needed for performing weight updates.

In mainstream frameworks including Theano, TensorFlow, Caffe, and CNTK the user first constructs a model as a computational graph using a domain-specific mini language, which then gets interpreted by the framework during execution. This approach has the advantage of enabling optimizations of the computational graph structure, but the disadvantages of having limited and unintuitive control flow and being difficult to debug. In contrast, the lineage of recent frameworks led by autograd, Chainer, and PyTorch provide truly general-purpose reverse mode AD, where the user directly uses the host programming language to define the model as a regular program of the forward computation. This eliminates the need for an interpreter, allows arbitrary control flow statements, and makes debugging simple and intuitive.

Simultaneously with the ongoing adoption of general-purpose AD in machine learning, we are witnessing a modeling-centric terminology emerge within the deep learning community. The terms define-and-run and static computational graph refer to Theano-like systems where a model is constructed, before execution, as a computational graph structure, which later gets executed with different inputs while remaining fixed. In contrast, the terms define-by-run and dynamic computational graph refer to the general-purpose AD capability available in newer PyTorch-like systems where a model is a regular program in the host programming language, whose execution dynamically constructs a computational graph on-the-fly that can freely change in each iteration.

Differentiable Programming is another emerging term referring to the realization that deep learning practice essentially amounts to writing program templates of potential solutions to a problem, which are constructed as differentiable directed graphs assembled from functional blocks whose parameters are learned from examples using gradient-based optimization. Expressed in this paradigm, neural networks are just a class of parameterized differentiable programs composed of building blocks such as feed-forward, convolutional, and recurrent elements.
